Abstract

Background
Early identification of risk for depression and anxiety disorders is important for prevention, but real-life affective well-being and its biological underpinnings in the population remain understudied. Here, we combined methods from epidemiology, psychology, ecological momentary assessment (EMA) and functional magnetic resonance imaging (fMRI) to study real-life and neural affective functions in individuals with subclinical anxiety and depression from a population-based cohort of young adults.

Methods
We examined psychological measures, real-life affective valence, fMRI amygdala habituation to negative affective stimuli and the relevance of neural readouts for daily-life affective function in 132 non-help-seeking community individuals. We compared psychological and EMA measures of 61 unmedicated individuals at clinical risk for depression and anxiety (operationalized as subthreshold depression and anxiety symptoms or a former mood or anxiety disorder) to those of 48 non-risk individuals and 23 persons with a mood or anxiety disorder. We studied risk-associated fMRI signals in subsamples with balanced sociodemographic and image quality parameters (26 non-risk, 26 at-risk persons).

Results
Compared to non-risk persons, at-risk individuals showed significantly decreased real-life affective valence ($p = .038$), reduced amygdala habituation ($p_{FWE} = .024$, region of
interest [ROI corrected] and an intermediate psychological risk profile. Amygdala habituation predicted real-life affective valence in controls, but not in participants at risk ($p_{FWE} = .005$, ROI corrected).

**Conclusions**

Our data suggest real-life and neural markers for affective alterations in unmedicated community individuals at risk for depression and anxiety and highlight the significance of amygdala habituation measures for the momentary affective experience in real-world environments.
1. Introduction

Early diagnosis, treatment and ideally prevention of psychiatric disorders in the population is desirable, but the existing knowledge about daily-life psychological and neural affective alterations in community-based individuals at mental health risk is limited (1). Meta-analyses suggest that about ten percent of all individuals in the general population experience subclinical symptoms of anxiety (2) and depression (3), and a significant proportion of these individuals will eventually transition to manifest psychiatric disorder (4, 5). However, many persons fall below the binary threshold of current diagnostic systems, which define the difference between mental health and disorder based on the presence of a predefined number and duration of psychiatric symptoms. Consequently, community-based individuals with daily-life subclinical symptoms often remain unnoticed and not sufficiently attended to, both in clinical and research settings (6).

From a community care and prevention standpoint, two groups of individuals are of particular relevance for the study of the underresearched “gray area” between mental health and disorder: Those who currently experience subthreshold symptoms but do not have a history of psychiatric illness, and those who have suffered from a psychiatric disorder in the past but do not currently experience any obvious clinical signs (1). In this work, we define these groups as community-based individuals at mental health risk. We derive this view from studies and discourses in the field that have critically addressed the clinical validity of diagnostic boundaries between normal and pathological mood and anxiety experiences (7, 8). Here, evidence suggests that there is a smooth transition between pathological depression and anxiety and milder emotional experiences (1), and that subthreshold prodromal and residual states carry a substantial risk of progression to more severe states over the life course (9, 10). In
our definition of mental health risk in the community, we thus put forward (and later
explore) the notion that both risk groups map to a shared (subclinical) continuum of
clinically relevant phenomena in between mental health and disease. At the biological
level, the grouping of the two at-risk groups is supported by studies showing
comparable abnormalities of subthreshold prodromal and residual states in social
reward processing (11, 12), in cognitive domains such as cognitive control and
executive function (13-16) and resting-state functional connectivity (17, 18). We further
propose that the improved understanding of the daily-life psychological and neural
characteristics of such risk states is important since the identification of salient risk
markers can guide the development of novel early interventions at multiple, synergistic
levels of influence, including in the areas of community mental health services, digital
mental health and neurofeedback therapy (19, 20).

Important leads for this work came from the recent literature, which emphasizes the
unspecific nature of symptoms at subclinical stages of psychiatric illness (1, 21, 22). In
addition, dimensional models of psychopathology such as the CHARMS (clinical high
at-risk mental state) concept served as important conceptual influence, which promote
the transdiagnostic investigation of subclinical risk markers and mechanisms to inform
future preventive and predictive approaches (22-24). Indeed, the existing data suggest
significant alterations in the daily-life experience in persons at clinical risk for mood
and anxiety disorders (25-27). These include, among others, higher negative affect
and lower hedonic capacity in real-world contexts, i.e., changes in daily experience
that can be addressed with e-health based interventions. At the neural system level,
altered habituation of the amygdala to threatening stimuli is a good candidate for
mechanistic investigation. This view is supported by the demonstrated reliability of the
phenotype (28) as well as its documented role as an evolutionarily conserved neural
mechanism for affective processing and behavioral adaptation (29, 30). Altered
amygdala habituation has further been associated with a range of psychiatric disorders and related risk constellations (31-35), including in community-based samples and across a dimensional range of symptom severity for anxiety, depression, and stress-related disorders (36-39). However, studies in community-based individuals at clinical risk are still scarce and the interpretation of existing data is often complicated by concomitant, interfering factors such as the preferential inclusion of help-seeking individuals or the contamination of neural readouts by confounding factors (e.g., treatment effects). Also, barely any study on this topic to date seized the opportunity of contemporary multimodal ecological neuroscience approaches, which allow for the coordinated inquiry of clinical, neural and daily-life psychological functions in naturalistic cohorts (25).

In the present study, we combined methods from epidemiology, clinical psychology, ecological momentary assessment (EMA) and functional MRI (fMRI) to study affective functions in community-based persons at clinical risk for depression and anxiety disorders derived from a population-based cohort of young, non-help-seeking adults. We used EMA with smartphone-based e-diaries to study momentary affective responses in real-world environments (40), used fMRI and a well-established implicit emotion processing task (41) to uncover alterations in amygdala signaling, and probed the significance of the identified neural phenotype for the affective experience in daily life.

We studied EMA and questionnaire data in 61 unmedicated individuals at clinical risk, 48 demographically similar non-risk persons and 23 community-based individuals identified as fulfilling the criteria for a current mood or anxiety disorder. We derived all study participants from the same naturalistic population by random selection. We
hypothesized that momentary affective valence in daily life would be significantly lower in the at-risk group and in the clinical group compared with the non-risk group. We further compared fMRI readouts between carefully matched subsamples of 26 unmedicated persons at clinical risk and 26 non-risk individuals to identify alterations in neural affective signaling related to community psychiatric risk in the absence of demographic, medication and image quality confounds. Here, we expected to see a blunted amygdala habituation in community-based persons at clinical risk reminiscent of that of clinical states (31, 32, 34). We further expected these neural affective signals to be relevant for the real-life affective experience of the non-risk individuals, the persons at clinical risk, or both groups. Beyond formal hypothesis testing, we further explored other EMA and questionnaire measures to yield novel insights into the nature and range of altered affective functions in community-based individuals at clinical risk.

2. Methods and Materials

2.1. Study participants and clinical assessment

The Psychoepidemiological Center at the Central Institute of Mental Health in Mannheim, Germany, recruited a total of 349 individuals for this study. Participants were young adults in the age range of 18 to 28 years, which we randomly drew from local population registries based on a two-stage proportionally layered procedure (see (40, 42) for details). General exclusion criteria were the presence of a relevant medical or neurological disorder. We assessed past and current psychiatric symptoms by screening forms and MINI-DIPS interviews (43-45) that were evaluated by two independent clinical raters (A.H., T.K.). The MINI-DIPS covers the most common mental disorders in adulthood according to ICD-10 and clarifies the presence of psychopathologically relevant experiences for the diagnostic categories. Based on these assessments, we defined four initial participants groups: 1) individuals with
current psychiatric symptoms above the diagnostic threshold (clinical group, n = 23, mean age: 23.17 ± 2.68 years, 20 females), 2) individuals with one or more current symptoms on the mood-anxiety spectrum that did not qualify for the diagnosis of a psychiatric disorder (subclinical group, n = 40, mean age: 22.37 ± 2.55 years, 33 females), 3) clinically remitted individuals with a personal history of relevant psychiatric symptoms in the past who denied the current presence of psychopathologically relevant experiences (history group, n = 21, mean age: 22.82 ± 3.01 years, 12 females), and 4) healthy non-risk individuals that were free of any current or former psychiatric symptoms, diagnosis or treatment (healthy non-risk group, n = 48, 21.86 ± 1.56 years, 39 females) that we derived from a larger sample of non-risk individuals.

We later combined the individuals of the subclinical and history groups to a joint group of community-based individuals at mental health risk since we expected that both groups would map on a shared continuum of affective alterations in between mental health and disease (24) (see Results and Supplemental Table S1). None of the at-risk individuals had received psychotropic medication in the preceding 12 months of study and only one of the persons was currently in formal psychiatric care (Supplemental Table S2). We then drew a sample of 48 individuals from the total pool of 264 identified non-risk individuals using internal software to achieve a non-risk group with a comparable distribution of basic sociodemographic characteristics (i.e., age, gender, education) to the combined at-risk group.

After study inclusion, we first collected questionnaire measures on time-stable psychological constructs. Subsequently, we collected EMA data over 7 days in everyday life. We performed the neuroimaging examination of the study participants immediately after the end of the EMA study week (i.e., 1.50 ± 1.36 (Min/Max=0/6) days
after EMA completion). We compared the acquired questionnaire and e-diary measures between the groups to identify psychological and real-life indicators of community mental health risk (Table 1). For the ensuing neuroimaging analysis of risk indicators, we compared subgroups of 26 at-risk and 26 non-risk individuals with available neuroimaging data that we carefully matched for a broader panel of sociodemographic attributes and data quality indicators known for impacting mental health-related neural readouts (e.g., fMRI task performance, fMRI image quality metrics [including tSNR, spikes, translation/rotation metrics and frame-wise displacement], socioeconomic status, current urbanicity, adverse childhood experiences, see Supplemental Table S3) (19).

The fMRI at-risk group included 18 individuals from the subclinical group and 8 individuals from the history group. All enrolled study participants provided written informed consent for a protocol approved by the Medical Ethics Committee II of the Medical Faculty Mannheim at the Ruprecht-Karls-University in Heidelberg, Germany.

**Psychological data acquisition and analysis**

We acquired a battery of well-established psychological and demographic questionnaires quantifying socioeconomic status (46), perceived social status (47, 48), degree of current urbanicity (49), trait anxiety (50), loneliness (51), self-efficacy (52), sense of coherence (53), optimism (54), perceived mental wellbeing (55), satisfaction with life (56), perceived daily hassles (57), chronic stress (58), coping strategies (59, 60), perceived social support (61) and retrospective self-ratings of adverse childhood experiences (62). We provide further details on the assessed questionnaires in Supplemental Table S4. We assessed group differences in SPSS (IBM, SPSS, version 25) using variable type and distribution appropriate tests (i.e., $\chi^2$ test, classical analysis of variance (ANOVA), Welch’s ANOVA, Kruskal-Wallis H test, see Table 1 for details).

**E-diary data acquisition and analysis**
We assessed e-diary-ratings for 7 consecutive days in daily life with study smartphones (Motorola Moto G, Motorola Mobility) and a flexible time and location-based sampling scheme with 9 to 23 prompts per day in between 7:30 AM and 22:30 PM (minimum/maximum interval: 40/100 minutes) as previously detailed (40, 42, 63). Our primary interest was to capture potential alterations in real-life affective valence in clinically at-risk individuals. For this, we used a well-known short scale for EMA with established psychometric properties (64) capturing within-subject fluctuations in real-life affective valence with the two bipolar items “content” to “discontent” (German translation: “zufrieden” – “unzufrieden”) and “unwell” to “well” (German translation: “unwohl” – “wohl”) presented at the edges of two computerized visual analogue scales with sliding locators (score range of 0 to 100). We instructed participants to place, upon each e-diary prompt, the locators at the scale positions representing their momentary affective state. We averaged the two item scores for use as dependent variable in our multilevel analyses.

For exploratory analysis, we further calculated an established EMA measure of daily-life affective (in)stability (i.e., the mean square of successive differences in valence, MSSD (65)) and assessed e-diary items quantifying momentary calmness and energetic arousal, social contact (63), social anhedonia (63), and the appraisal of negative and positive events (66, 67). E-diaries and sampling strategy were implemented with the ambulatory assessment software movisensXS (version 0.6.3658, movisens GmbH, Germany). We used multilevel models in SAS (version 9.4, SAS Institute Inc., Cary, NC, USA) to test for group differences, thereby nesting within-subject e-diary assessments (level 1) within participants (level 2), and using a categorical group variable (level 2) (68). We provide further details on the EMA acquisition and analysis methods in the Supplemental Information. All participant
groups surpassed an average compliance rate of 70% and we covaried for between-group differences in compliance in our multilevel analysis (Table S5).

**fMRI data acquisition and preprocessing**

We performed blood oxygen level–dependent fMRI on a 3T MRI scanner (Siemens Trio, Erlangen, Germany) using a well-established implicit emotion processing paradigm with two task conditions (emotional face matching, shapes matching) (41) providing reliable measures of amygdala habituation (28). We processed and analyzed the fMRI data with SPM12 (www.fil.ion.ucl.ac.uk/spm) implemented in MATLAB (The MathWorks, Inc., Natick, MA). Data preprocessing consisted of standard procedures. We provide further methods details on the employed fMRI sequence, paradigm and preprocessing routines in the *Supplemental Information*.

**Amygdala activation and habituation analysis**

fMRI data analysis consisted of a two-level procedure. At the first level, we defined a general linear model (GLM) for each subject that included the boxcar reference vectors for the task blocks of the two conditions (convolved with the standard SPM hemodynamic response function) and the 6 head motion parameters from the realignment step (covariates of non-interest). During model estimation, we defined a high-pass filter with a cut-off frequency of 262s to remove low frequency signal components and used first-order autoregressive (AR[1]) modeling to correct for temporal autocorrelations. We computed individual maps of voxel-wise habituation indices as previously described (28) by calculating the mean response amplitude difference between the first and the last block of the face matching condition ([block 1 > block 4]. At the second level, we entered these maps into univariate ANOVA models with group (clinical at-risk, non-risk) as factor. Consistent with our previous work (31), we defined a group contrast to test for the hypothesized amygdala habituation deficits in community-based individuals at clinical risk (clinical at-risk < non-risk). We further
tested for general and group-specific associations between daily-life affective valence and amygdala habituation estimates. For this we used univariate ANOVA models with the mean individual EMA-derived valence measures and a corresponding interaction term (group x valence) as regressors of interest, respectively.

**fMRI Statistical Inference**

We assessed statistical significance at $p < 0.05$, peak voxel-level familywise error (FWE) corrected for multiple comparisons within an a priori defined anatomical region of interest (ROI) mask of the right amygdala derived from the Wake Forest University (WFU) PickAtlas (69). As in our previous work (31), we chose the right amygdala as a priori ROI for hypothesis testing since the literature suggests a different functional role and habituation rate for the right amygdala, with a specialization for the rapid and dynamical detection of affective stimuli (70-72) and a higher retest reliability of habituation estimates (28).

3. Results

**Psychological questionnaire data**

Descriptive analysis of psychological data revealed a regular pattern across variables, with the group means of the at-risk group mapping in between those of the non-risk group and the clinical group, respectively. Inferential statistics revealed significant differences of the at-risk group for daily hassles, maladaptive coping and perceived loneliness compared to the non-risk group (all $p$s < .016, all reported $p$ values are Bonferroni corrected for multiple group comparisons) but not the clinical group (all $p$s > .31). In contrast, in other psychological variables such as perceived mental well-being, satisfaction with life, optimism, self-efficacy and social support at-risk persons did not differ significantly from the non-risk group (all $p$s > .12) but differed significantly from the clinical group (all $p$s < .05). For trait anxiety and dispositional sense of
coherence, the at-risk individuals displayed fully intermediate properties, in that they differed significantly from both the non-risk group and the clinical group (all $p$s < .001). We provide further statistical details in Table 1. There were no significant group differences in psychological questionnaire data between the community-based subgroups at mental health risk (i.e., subclinical group vs. history group, see Supplemental Table S2 for details).

**Daily-life ecological momentary assessments**

Daily-life affective valence in the at-risk individuals was significantly lower than that of the non-risk group ($p = .038$, all $p$ values are Bonferroni corrected for multiple group comparisons) and significantly higher than that of the clinical group ($p = .012$) (Figure 2B). Exploratory analyses suggested no group differences in the frequency of social contacts and the appraisal of positive events (all reported $p$s > .67). We further did not detect any group differences between the at-risk group and the non-risk group for affective (in)stability, negative event appraisal, liking of social contact, preference of being alone and momentary feelings of calmness and energetic arousal (all $p$s > .11). In contrast to this, individuals in the clinical group exhibited widespread changes in these variables, which distinguished this group from both the at-risk and non-risk groups. We provide further statistical details in Table 1 and Supplemental Table S5.

**Amygdala habituation analyses**

Comparison of the at-risk group and the non-risk group confirmed a significant reduction of right amygdala habituation to repeated negative affective stimuli in the at-risk individuals ($t = 3.03$, $p_{FWE} = .024$, all reported $p$ values are peak-level corrected for region of interest) (Figure 1B). This finding also survived correction for a bilateral amygdala mask ($t = 3.03$, $p_{FWE} = .047$). In the non-risk individuals, data inspection suggested a high initial responsivity of the right amygdala followed by a rapid decline in activity with successive emotional block repetitions, whereas in the at-risk individuals
the amygdala responsivity appeared blunted and uniform over time (Figure 1C). A regression analysis with daily-life affective valence scores as a predictor did not provide evidence for a significant association with amygdala habituation across all individuals ($t = 1.96, p_{FWE} = .330$). However, we detected a significant group by EMA valence interaction effect on right amygdala habituation ($t = 3.70, p_{FWE} = .005$; after correction for a bilateral amygdala mask: $t = 3.70, p_{FWE} = .009$) (Figure 2). Post-hoc regression analysis confirmed that higher right amygdala habituation was significantly related to higher daily-life affective well-being in the non-risk group ($t = 3.33, p_{FWE} = .012$; after correction for a bilateral amygdala mask: $t = 3.33, p_{FWE} = .024$) but not in the at-risk group ($t = 0.96, p_{FWE} = 0.76$).

**Discussion**

In this study, we took a multimodal ecological neuroscience approach to identify psychological, real world, and neural markers of altered affective function in unmedicated individuals at clinical risk for mood and anxiety disorders drawn from a population-based cohort of young adults. Specifically, we aimed to characterize the psychological profile of at-risk individuals in the community, determine the nature and extent of their current affective alterations in daily life, and examine the relevance of the neural signals examined to real-world affective experience. We obtained several interesting results, which we discuss below.

In terms of psychological profile, we posited that community-based individuals at clinical risk are on a continuum of change that spans between healthy non-risk individuals and individuals with a current manifest disorder. At the descriptive level, we observed just this: mean scores for the risk group were intermediate between those of the other two groups in all variables, and our supplemental analysis revealed no
significant differences between the “history” and “subclinical” subgroups, which we combined into one risk group. At the same time, the areas in which at-risk persons differed significantly from the non-risk individuals were relatively specific, while the group with a manifest disorder showed clear changes in almost all of the areas examined. Specifically, significant differences in risk individuals clustered around variables indicating heightened stress awareness, a tendency to negative emotions and a limited ability to use personal resources to cope with such experiences. These focal differences presented against a background of mostly unremarkable functions and resources, such as preserved satisfaction with life, optimism and social support. We conclude from these data that psychological alteration in the community is a gradual phenomenon, and that the psychological profile of individuals with subclinical mood and anxiety symptoms is comparable to that of fully remitted individuals with a previous mood or anxiety disorder. Further, the clearly salient psychological deficits of community-based individuals at clinical risk appear selective and involve the processing of stress and negative emotions.

Regarding the nature and extent of daily life impairments, we hypothesized that young community-based individuals with subclinical depression and anxiety would show a significant reduction in affective valence, and our study results confirmed this assumption. Although there are few comparable studies to date, this finding aligns well with our own findings on the impact of psychiatric risk and resilience factors on real-life affective valence (40, 73) and changes in emotional experience of children and adolescents with subclinical symptoms reported in other community-based EMA studies (74-76). In relative terms, our exploratory analysis of other EMA outcomes further suggests selective changes in the daily-life experience of community-based individuals at clinical risk. Precisely, while the clinical group differed significantly in
almost all measures recorded, including those indicative of daily-life depressed mood, reduced drive, social anhedonia, affective instability, and increased stress experience, the decrease in affective valence in the at-risk subjects seemed to occur against a background of otherwise unremarkable real-life functions. Together with the psychological profile elaborated above, this suggests that community-based individuals at increased risk for mood and anxiety disorders exhibit selective risk phenotypes on the behavioral and experiential level, including limited personal resources to cope with stress-associated experiences and a reduction in affective valence in daily life. In addition to traditional psychotherapy, deficits in the daily-life experience can be addressed with targeted ecological moment interventions (EMI), especially when the real-world “risk marker” or target phenomenon is known, as in this case (77).

At the neural systems level, our results identify reduced amygdala habituation in community-based individuals with subclinical depression and anxiety. Specifically, whereas the non-risk group showed a decrease in estimated amygdala response of about 60%, it was only 1% for the risk subjects (emotional stimulation block 1 - 4). The amygdala plays an evolutionarily conserved role in threat processing (78) and the robust habituation phenotype studied (28) reflects a basic neural plasticity mechanism that supports a basic and innate form of learning. Specifically, it protects the organism from repeatedly responding to threat-associated stimuli with no meaningful consequences for survival, thereby freeing up important neural and behavioral resources for more pressing tasks. The detected difference in habituation in community-based individuals at risk is thus suggestive of a neural plasticity-related alteration in the affective processing of environmental stimuli in this group. In our non-risk individuals, amygdala response habituated as expected and predicted increased
momentary affective valence, indicating the relevance of this neurofunction in daily life. This link was not found in our community-based individuals at clinical risk, whose diminished real-life affective well-being was unrelated to amygdala habituation. Although further experiments will be necessary to determine the origin of this dissociation, we speculate that reduced biological plasticity in the amygdala may require alternative regulatory strategies to deal with perceived threat (e.g., cognitive appraisal), which may disrupt the direct link of amygdala habituation to real-life affective well-being. Deficient amygdala habituation as such is unlikely specific to certain psychiatric disorders (31, 79) or sources of illness risk (31, 80, 81). However, since amygdala function can be directly targeted and modulated with neurofeedback-based interventions (82), this neural risk phenotype is an attractive candidate for novel multimodal treatment (and ideally prevention) concepts with multiple, synergistic starting points.

The results presented must be evaluated against the background of some limitations of our study, which we explain below. First, the size of the studied groups is limited. This is mainly because we obtained our participants from an epidemiological sample of young adults in the population, in which the prevalence of subclinical syndromes and full remissions of a previous disorder is finite. Second, we departed from a purely population-based approach by matching the composition of the non-risk comparison group using a set of predefined demographic and treatment-related variables. We consider both of these decisions important because we wanted to reflect as closely as possible the situation of young, non-help-seeking, and clinically vulnerable individuals in the community, while minimizing bias in our results from confounding variables that are known to affect the outcomes we studied. Third, we could not consistently apply the three-group design of the questionnaire and EMA analyses in neuroimaging space because we did not have enough usable fMRI data from the clinical group. However,
because our primary goal was to study a neuronal risk marker in individuals from the general population in the absence of treatment effects, the availability of sufficient patient data for this purpose would have been of limited help anyway. Fourth, beyond affective valence, the reported EMA results are based on exploratory analyses, and any interpretations based on these findings are therefore preliminary. However, we felt it was important to report these data and our opinions in this regard, as they may promote the formation of new hypotheses in future studies. Finally, the reported associations between neural and everyday affective measures are based on cross-sectional data and therefore do not allow for causal interpretations. We speculate that the relationship between brain function and everyday experience is a complex, reciprocal causal process, an assumption that should be further explored in future experimental studies.

**Figure 1.** Group differences in amygdala reactivity changes to threatening stimuli over the course of the functional magnetic resonance imaging experiment. Significant difference in amygdala habituation manifesting as a rapid signal decrement to successive emotional stimulation blocks in the community-based individuals not at clinical risk (non-risk group) but not the community-based at clinical risk (at-risk group) ($t = 3.03, p_{FWE} = .024$). The functional map is thresholded at $p = .005$, uncorrected for illustration purposes, and is displayed on the coronal section of a structural-template magnetic resonance image. The plot shows habituation estimates (and standard errors of the mean) of the peak voxel in the right amygdala for each fMRI task block and group, respectively. FWE, family-wise error. MNI, Montreal Neurological Institute standard space.

**Figure 2.** Study methods and amygdala habituation–affective valence associations. (A) Illustration of the smartphone-based assessment of affective valence in daily life in connection with a person’s movement pattern in downtown Mannheim. Left: Visualization of the affective valence and social contact e-diary items. Smartphone image by ElisaRiva (http://www.pixabay.com). Right: White check marks on a red background displayed on the route symbolize positions where e-diary assessments were prompted (for illustration purposes, not real study participant). (B) Significant group differences in EMA valence between community-based individuals not at clinical risk, those at clinical risk, and those with a current mood or anxiety disorder. Community-based individuals at clinical risk display significantly lower valence levels than non-risk persons, and significantly higher valence levels than individuals in the clinical group; error bars display standard error (SE) from the MLM (for details see Table 1). (C, D) Differential association of amygdala habituation and affective valence in daily life in community persons at clinical risk compared to those not at risk ($t = 3.70, p_{FWE} = .005$). The functional map in panel (C) is thresholded at $p = .005$, uncorrected for illustration purposes, and is displayed on the coronal section of a structural-template magnetic resonance image. The scatterplot in panel (D) depicts the associations of the habituation estimates (extracted from the amygdala peak voxel) and valence values for the two groups. The reported interaction analysis finding in imaging space also survived FWE correction after excluding one outlier from the analysis. FWE, family-wise error. MNI, Montreal Neurological Institute standard space.

Broad-based changes in the clinical group on most outcome measures compared with limited changes in the at-risk group in areas involving stress experience, negative emotions, and personal coping skills. For details on the psychological questionnaires including acronyms, see Supplemental Table S4. Abbreviations: M = mean, SD = standard deviation, n = number of participants with available data, ANOVA = univariate analysis of variance, χ² = chi-squared test, H-test - Kruskal-Wallis Test. MLA = multilevel analysis controlling for the time of day and time of the day-squared (level 1); and controlling for differences in compliance (level 2). MSSD valence = mean square of successive differences of valence ratings.

*Employed tests: χ² tests for group comparisons with categorical variables, ANOVA and Tukey tests for group comparisons and variables with equal variance and normal distribution. Welch-ANOVA and Games-Howell tests for group comparisons with normally distributed variables with unequal variance (as identified by Levene-test), Kruskal- Wallis and Dunn tests for group comparisons with not-normally distributed variables with (un)equal variance.

⁴All p-values of post-hoc pairwise group comparisons are Bonferroni corrected for multiple group comparisons.

⁵Aggregation of EMA indices within and between subjects for use for sample description only.

Mean/day/participant

Number of prompts participants have been alone out of all prompts across 7 days of measurement

Percent of answered prompts.
